**ABSTRACT**

For the first time, we systematically explored the population of discrete X-ray sources in the outskirts of early-type galaxies. Based on a broad sample of 20 galaxies observed with *Chandra* we revealed overdensity of X-ray sources in their outskirts. They appear as halos of resolved sources around galaxies, distributing much broader than the stellar light, and extended out to at least ~ 10σ, (σ is the effective radius). These halos are composed of sources fainter than ~ 5 × 10⁻¹⁸ erg/s, whereas the more luminous sources appear to follow the distribution of stellar light, suggesting that the excess source population consists of neutron star binaries. Dividing the galaxy sample into four groups according to their stellar mass and specific frequency of globular cluster, we find that the extended halos are present in all groups except for the low mass galaxies with low globular cluster content. We propose that the extended halos may be comprised of two independent components: (i) LMXBs located in blue (metal-poor) globular clusters (GCs), which GCs are known to have a broader distribution than the stellar light; (ii) neutron star LMXBs kicked out of the main body of the parent galaxy by the supernova explosion. The available deep optical and X-ray data of NGC 4365 supports this conclusion. For this galaxy we identified 60 ± 10.8 excess sources in the (4 – 10)σ region of which ~ 40% are located in globular clusters, whereas ~ 60% are field LMXBs. We interpret the latter as kicked NS LMXBs. We discuss implications of these results for the natal kick distributions of black holes and neutron stars.

**Key words.** X-rays:binaries - globular clusters: general - Galaxy: halo - supernovae: general

---

1. **Introduction**

LMXBs consist of a compact object – either a black hole (BH) or a neutron star (NS) – and a low-mass donor star (≤ 1 M☉), which transfers mass via Roche-lobe overflow. The infalling matter is heated to X-ray temperatures and releases X-ray luminosities in the range of 10⁻³⁴ – 10⁻³⁹ erg/s. Due to their luminous nature, LMXBs add a major contribution to the total X-ray emission of galaxies, moreover they determine the X-ray appearance of relatively gas-poor early-type galaxies (e.g. Gilfanov 2004; Bogdán & Gilfanov 2011). The populations of LMXBs have been extensively studied in early-type galaxies with *Chandra* observations (e.g. Irwin et al. 2003; Gilfanov 2004; Zhang et al. 2011; Colbert et al. 2004) and a simple picture of the correlation of their properties with the parameters of the host galaxy emerged. It has been established that LMXB population scales with the stellar mass of the host galaxy. For luminous LMXBs (L_X > 3 × 10⁻³⁸ erg/s), it has also been shown that their surface density closely follows the near-infrared light distribution (Gilfanov 2004), except for the very inner regions of galaxies (Voss & Gilfanov 2007). However, in the course of more than ten years of operation of *Chandra*, a large number of early-type galaxies has been observed to a fairly deep sensitivity limit (L_X > 10⁻³⁶ erg/s), allowing to probe LMXB populations in unprecedented detail.

Such a detailed study of LMXB populations has been performed for Sombrero galaxy (M104) by Li et al. (2010). Their results appear to challenge the empirical picture that the LMXB populations closely follow the stellar light distribution at all galactocentric radii. As opposed to the expectations, the outskirts of Sombrero exhibits a significant X-ray source excess. In the halo of this galaxy 101 sources were detected, whereas the expected number of cosmic X-ray background (CXB) sources is 52 ± 11, implying ~ 4.4σ excess. Although Li et al. (2010) did not identify the origins of the excess X-ray sources, they considered that either supernova kicked binary systems and/or LMXBs associated with GCs could be responsible.

GCs have a bimodal color distribution (Forbes et al. 1997). The red (metal-rich) population follows the stellar light distribution, whereas the blue (metal-poor) population has broader distribution and traces the more extended dark matter halos (e.g., Bassino et al. 2006). Since few percent of blue GCs host LMXBs (Kundu et al. 2012; Jordán et al. 2004), it is likely that LMXBs associated with blue GCs will have a broader distribution than the stellar light. This effect could result in an extended population of LMXBs in the outskirts of galaxies. Obviously, the importance of GC-LMXBs is expected to be more prominent in galaxies with higher globular cluster specific frequency (SN).

Neutron stars receive kicks (so called natal kicks) when they are formed in the core collapse supernova explosions. The amplitude of the natal kick velocities can be determined, for example, from proper motion of pulsars, the mean birth speed for young pulsars is ≈ 400 km/s with the fastest neutron stars moving with the velocity in excess of ~ 10⁴ km/s (Hobbs et al. 2005). Although only a relatively small fraction of binary systems can survive large natal kicks (Brandt & Podsiałowski 1995), those do survive, can travel to large distances producing a distribution...

2. The analyzed sample

In this paper, we aim to comprehensively explore the LMXB populations in a large sample of galaxy outskirts with the limiting sensitivity of ~ 10^37 erg s^{-1}. We will address two major points. First, we will investigate whether the existence of excess LMXBs is ubiquitous in the outskirts of early-type galaxies. Second, we will study the origin of the excess sources with a particular focus on GC-LMXBs and supernova kicked X-ray binaries. To achieve our goals, we will use a sample of 20 early-type galaxies with deep Chandra observations. Since our galaxy sample covers a broad range in both stellar mass and globular cluster specific frequency, we will be able to perform a systematic study and address the importance of GC-LMXBs and supernova kicked LMXBs.

In the present work we explore the LMXB populations in the outskirts of early-type (E/S0) galaxies. To achieve this goal and obtain statistically significant conclusions, a broad sample of galaxies must be analyzed. In Zhang et al. (2012) we carefully built a sample of 20 galaxies, which also well suits the pursued goals of the present analysis for the following four reasons. First, the sample consists of galaxies within the distance range of 9.7–27.7 Mpc. Therefore, adequate (~ 5 × 10^37 erg s^{-1}) source detection sensitivities can be achieved with moderately deep (< 150 ks) Chandra exposures, and the sample galaxies and their outskirts fit well within the ACIS field-of-view. Second, the sample includes both GC-rich and GC-poor galaxies (S_N = 0.50 – 12.38). Third, the sample covers a relatively broad range of stellar masses (M_* = (6.1 – 35.6) × 10^10 M_☉), implying vastly different numbers of field LMXBs, as well as different dark matter halo masses. Finally, the selected galaxies do not exhibit ongoing or recent star-formation, hence their stellar content is fairly homogeneous and the population of X-ray binaries is not polluted by high-mass X-ray binaries. The physical properties of the sample galaxies are listed in Table 1.
Several galaxies in our sample have been observed in multiple Chandra observations and the main steps of the data analysis agree with those outlined in [Zhang et al. 2012]. The data was reduced using standard CIAO threads (CIAO version 4.2; CALDB version 4.2.1). To detect point sources, we applied the CIAO wavdetect task with parameters taken from Voss & Gilfanov (2006, 2007). Namely, we set the threshold parameter (sigthresh) to 10^4.5, which implies 1 false detection per 10^6 pixels or one ACIS-S CCD. The source detection was performed in the 0.5 – 8 keV band. To increase the source detection sensitivity, we did not include high background periods, since they are outweighed by the increased exposure time. We produced exposure maps in the 0.5 – 8 keV band, assuming a single power-law model with Γ = 1.7 and Galactic absorption. Several galaxies in our sample have been observed in multiple Chandra pointings, therefore we corrected the offsets following Voss & Gilfanov (2007) using the CIAO reproject_events tool. After correcting the offsets, the images were combined and reanalyzed.

To compute the source net counts, we employed circular apertures centered on the central coordinates of each source. The radius of the aperture was defined as a circle, which includes 85% of the point spread function (PSF) value. For each source, the PSF was determined using the CIAO mkpsf tool. To account for the background components, we applied circular regions with three times the radius of the source regions, while the overlapping regions of adjacent sources were excluded. The source net counts were derived following Voss & Gilfanov (2007). The observed net counts were converted to 0.5 – 8 keV band unabsorbed luminosities assuming a power-law spectrum (Γ = 1.7) with Galactic absorption.

The source detection sensitivity varies throughout the Chandra images due to the varying level of the diffuse X-ray emission associated with the galaxy, the PSF deterioration at large off-axis angles, and the non-uniform exposure of the (combined) images. For the combined images, we derived the source detection sensitivities by inverting the detection method, using the local PSF, background, and exposure [Voss & Gilfanov 2006]. The incompleteness function, K(L), in a certain area was calculated by accumulating the sensitivities of the pixels included in the area, weighted by the assumed spatial distribution of sources. Thus, K(L) was computed separately for the CXB sources with a flat spatial distribution, and for LMXBs assuming that they follow the Ks-band stellar light. We used these functions to calculate the number of predicted CXB sources [Georgakakis et al. 2008] and LMXBs (Table 2), and to obtain their predicted radial source density profiles (Sect. 4.1). The incompleteness function was also used to correct apparent X-ray luminosity functions (XLFs), and to produce the final XLFs presented in Sect. 5.2.

The contribution of CXB sources is estimated based on their luminosity function from Georgakakis et al. (2008). To convert their 0.5 – 10 keV band log N – log S distribution to the 0.5 – 8 keV band, we assumed a power-law model with Γ = 1.4. Within the central regions of the galaxies, the contribution of CXB sources is ≤ 10% (Table 2). Although in the outskirts of the sample galaxies the ratio of predicted CXB sources is significantly higher (Table 2), in most galaxies a statistically significant source excess is detected above the predicted CXB level. We stress that the excess sources cannot be attributed to the cosmic variance, which can be responsible for variations on the ~ 10 – 30% level. The accuracy of CXB subtraction is further discussed in Sect. 5.1.

3.2. Near-infrared data analysis

To trace the stellar light of the sample galaxies, we relied on the Ks-band (2.16 μm) images of the 2MASS Large Galaxy Atlas [Jarrett et al. 2003]. The provided images are background subtracted, except for NGC 821 and NGC 1052, where we estimated the background level using nearby regions. To avoid pollution by bright foreground and background objects, we visually identified and removed them. We converted the observed number of Ks-band source counts (S) to apparent magnitudes using mKs = KMAGZP – 2.5 log S, where KMAGZP is the zero point magnitude for the Ks-band image. The thus obtained magnitudes were used to compute Ks-band luminosities, assuming that the absolute Ks-band magnitude of the Sun is KM = 3.39 mag.

Based on the Ks-band luminosities and the Ks-band mass-to-light ratios, we derived the stellar mass of the sample galaxies (Table 1). The mass-to-light ratios were derived from the B – V color indices (RC3 catalog; de Vaucouleurs et al. 1991) and the results of galaxy evolution modeling [Bell & de Jong 2001].

4. Excess X-ray sources in galaxy outskirts

4.1. Radial distributions of all galaxies

To map the spatial distribution of X-ray sources in and around the sample galaxies, we built stacked radial source density profiles (Fig. 1). The profiles were extracted from concentric ellipses, whose shape and orientations were determined by the Ks-band photometry of the galaxies (Table 1). The contribution of CXB sources was subtracted as described in Sect. 5.1. The ob-

Notes. (1) – Number of detected X-ray sources, estimated CXB sources, and estimated LMXBs from Ks-band light in the (0.2 – 3)r\textsubscript{e} region. (4) – The same quantities in the (4 – 10)r\textsubscript{e} region.
of faint sources at large radii. The origin and characteristics of distribution at all radii, being in good agreement with Gilfanov the faint excess sources are discussed throughout the paper. Observed distribution of bright sources follows the stellar light. However, at the time of writing, only relatively shallow Chandra observations of early-type galaxies were available, hence Gilfanov (2004) considered only bright X-ray sources. In the lower panel of Fig. 1, we present the radial source density profile of Gilfanov (2004), who concluded that the distribution of LMXBs closely follows the stellar light. However, at the time of writing, only relatively shallow Chandra observations of early-type galaxies were available, hence Gilfanov (2004) considered only bright X-ray sources. The observed distribution of bright sources follows the stellar light distribution at all radii, being in good agreement with Gilfanov (2004).

Figure 1 clearly shows that there is an excess in the number of faint sources at large radii. The origin and characteristics of the faint excess sources are discussed throughout the paper.

4.2. Source excess in individual galaxies

In Fig. 1 we demonstrated the existence of an excess population of faint sources beyond \(4r_e\). However, the presented stacked source density profiles were obtained for 20 galaxies, hence it reflects the general behavior of our sample. To study individual galaxies, we derived the number of detected and predicted X-ray sources in each galaxy separately. Given the relatively low number of detected sources in individual systems, we did not attempt to build radial source density profiles for each galaxy. Instead, we divided the galaxies into two regions: the inner region was defined as an elliptic annulus with \((0.2 - 3)r_e\) radius, whereas the outer region is an elliptic annulus with \((4 - 10)r_e\). Note that the central \(0.2r_e\) region was excluded to avoid the possible source confusion. The results are summarized in Table 3 where we list the numbers of detected sources, predicted LMXBs, and estimated CXB sources in the inner and outer regions. As before, the predicted numbers of LMXBs were derived using the average LMXB XLF (Zhang et al. 2011) and the stellar mass enclosed in the regions. The estimated CXB level was derived as described in Sect. 3.1.

In the inner region the numbers of detected and predicted X-ray sources agree within \(\sim 50\%\) for all galaxies, except for NGC 4382, NGC 4636, and NGC 4649, where they agree within factor of \(\sim 2\). In the entire sample, the total number of LMXBs in the inner region after CXB subtraction is 1327.6, whereas the expected number is 1217.3, which numbers agree within \(\sim 10\%\). The total stellar mass in the \((0.2 - 3)r_e\) region is \(2.1 \times 10^{12}\) \(M_\odot\), implying a sample-averaged LMXB specific frequency of \(6.3 \pm 0.2\) sources per \(10^{10}\) \(M_\odot\). In agreement with Gilfanov (2004), the ratio of \(N\) observed to predicted LMXBs in the inner region after CXB subtraction is 1.2. The total predicted number of LMXBs by factor of \(2.5 - 6\), and in NGC 4636 and NGC 4649 this ratio is even larger. In the outer region we detected 609.4 X-ray sources after subtracting the CXB level, whereas 158.1 sources are expected, implying a factor of \(\sim 3\) excess. The total enclosed stellar mass in the outer region is \(2.1 \times 10^{11}\) \(M_\odot\), hence the sample-averaged LMXB specific frequency is \(29.0 \pm 1.2\) sources per \(10^{10}\) \(M_\odot\), which is \(\sim 3.5\) times more than in the inner region.

Based on the study of individual galaxies, we obtain two major conclusions. First, the existence of excess X-ray sources appears to be a general phenomenon in the outskirts of galaxies. Second, the LMXB specific frequency is, on average, by a factor of \(\sim 3.5\) higher in the outer region than in the inner region, indicating that the excess X-ray sources do not originate from CXB fluctuations, and are not directly associated with the stellar populations in the outskirts of studied galaxies.

4.3. The role of supernova kicks and GC-LMXBs

There are at least two plausible factors which could be responsible for the observed excess in the surface density of X-ray source excess in the galaxy outskirts. They could be LMXBs residing in globular clusters and/or accreting NS binaries that were kicked to large galactocentric radii by the supernova explosion, which produced the NS. The importance of GC-LMXBs is, on average, by a factor of \(\sim 3.5\) higher in the outer region than in the inner region, indicating that the excess X-ray sources do not originate from CXB fluctuations, and are not directly associated with the stellar populations in the outskirts of studied galaxies.

In the inner region we demonstrated the existence of an excess population of faint sources beyond \(4r_e\). 4.3. The role of supernova kicks and GC-LMXBs

There are at least two plausible factors which could be responsible for the observed excess in the surface density of X-ray source excess in the galaxy outskirts. They could be LMXBs residing in globular clusters and/or accreting NS binaries that were kicked to large galactocentric radii by the supernova explosion, which produced the NS. The importance of GC-LMXBs is, on average, by a factor of \(\sim 3.5\) higher in the outer region than in the inner region, indicating that the excess X-ray sources do not originate from CXB fluctuations, and are not directly associated with the stellar populations in the outskirts of studied galaxies.
Fig. 2. Stacked radial source density profiles of the CXB subtracted LMXBs in four groups of galaxies with different $M_*$ and $S_N$, marked in the plots. The profiles are not corrected for incompleteness. The predicted distributions of LMXBs based on the $K_s$-band light are plotted with solid histograms. They take into account the source detection incompleteness, as described in the Sect. 3.1. All groups show excess LMXBs in their outskirts, except for galaxies with small $M_*$ and small $S_N$.

$M_*$ and small $S_N$, 3) small $M_*$ and large $S_N$, and 4) small $M_*$ and small $S_N$.

For each group, we derived stacked radial profiles of the detected X-ray sources and computed the predicted number of LMXBs as described in Sect. 4.1. The obtained profiles are depicted in Fig. 2. A common property of the four groups is that in the inner region the observed and estimated profiles are in fairly good agreement. However, in the outer region the first three groups show a significant source excess, with the only exception being low-mass galaxies with low $S_N$. Thus, we conclude that the X-ray source excess cannot be only associated with either GC-LMXBs or supernova kicked LMXBs, but both types of sources play a role.

5. Combined XLFs of LMXBs

5.1. Accuracy of the CXB subtraction

To further explore the properties of LMXBs in the sample galaxies, we built combined XLFs of all the sources residing in the inner ($0.2 – 3) r_e$ and outer ($4 – 10) r_e$ regions. In total, we resolved 1412 and 1077 point sources in the inner and outer regions (Table 2), allowing us to build accurate XLFs.

Since our study is focused on galaxy outskirts with relatively low source density, it is crucial to accurately account for the CXB level. In the inner regions the estimated average contribution of CXB sources is only $\sim 6\%$, whereas it is $\sim 43\%$ in the outer regions (Table 2). Given that the CXB source density exhibits $10 – 30\%$ field-to-field variations due to the cosmic variance, the inaccurate subtraction of the CXB level could significantly influence our study. Therefore, in Fig. 3 we show the combined cumulative luminosity distributions of the detected X-ray sources in the inner and outer regions, which are compared with the predicted, incompleteness-corrected CXB source distributions. The upper panel of Fig. 3 demonstrates that in the inner region the contribution of CXB sources is fairly low at luminosities below $10^{39} \text{ erg s}^{-1}$. Above this threshold we detected ultra-luminous X-ray sources, which are most likely stellar mass black holes accreting from a low or intermediate mass companion. For a comprehensive discussion of these ultra-luminous X-ray sources we refer to Zhang et al. (2012).

The lower panel of Fig. 3 shows that in the outer region the luminosity distribution of sources above $5 \times 10^{38} \text{ erg/s}$ is in excellent agreement with the predicted CXB level. Indeed, above this luminosity $71\pm8.4$ X-ray sources are detected, whereas 65.1 CXB sources are predicted. Note that in the bright end the XLF is not affected by incompleteness effects. Below $5 \times 10^{38} \text{ erg/s}$

\begin{table}[h]
\centering
\begin{tabular}{ll}
\hline
\hline
Galaxy Group & N Source  \\
\hline
\hline
N0720 N1404 N3585 N4125 N4382 & N3115 N4278 N4552 N4636 N4697 \\
\hline
\end{tabular}
\end{table}
the number of detected sources is more than a factor of two of
the expected number of CXB sources. Thus, in agreement with
the radial source density profiles (Fig. 1), the XLF also shows
the presence of an excess source population with luminosities
< $5 \times 10^{38}$ erg/s in the outer region. The good agreement
between the observed source and predicted CXB luminosity
distributions in the bright end demonstrates the accuracy of our
CXB subtraction procedure. Moreover, the large difference between the XLFs
in the faint end excludes the possibility that the observed excess
is due to the cosmic variance.

5.2. Source XLFs of the inner and outer regions

We directly compare the combined XLFs of all galaxies in the
inner and outer regions in Fig. 4. To build the XLFs, we only
considered detected X-ray sources above the 0.6 incompleteness
level. The sources observed in individual galaxies were
combined and weighted with the enclosed stellar mass within
the regions following Zhang et al. (2011). We subtracted the
CXB level and applied incompleteness correction as described
in Sect. 3.1. In the upper and lower panels of Fig. 4 we show the
final cumulative and differential forms of the XLFs, respectively.

Although statistical uncertainties at high luminosities are
rather large, the XLFs of the inner and outer regions appear to
be consistent with each other in the bright end. This conclusion
is further supported by the luminosity distributions shown in the
Fig. 3 and the shape of the radial profile of bright sources in the
Fig. 1. On the other hand, the outer region shows a significant
source excess in the luminosity range below $\sim 5 \times 10^{38}$ erg/s.
This threshold luminosity is fairly close to the Eddington lumi-
nosity of an accreting NS. Therefore, it is reasonable to assume
that the bulk of faint excess sources are NS binaries. This con-
clusion is consistent with the proposed origin of excess sources.
Indeed, both GC-LMXBs (Portegies Zwart & McMillan 2000)
and supernova kicked binaries (Brandt & Podsiadlowski 1995)
are predominantly NS binaries.

In principle, it would be beneficial to compare the XLFs of
the four groups of galaxies with low/high $M_\star$ and $S_N$. The shape
of the XLFs could help to constrain the origin of the excess
sources, since field and GC-LMXBs exhibit markedly different
XLFs at luminosities below few times $10^{37}$ erg/s (Zhang et al.
2011). However, the studied sample is not suitable for such a
comparison since the source detection sensitivity of most sam-
ple galaxies is comparable to this luminosity limit. Above few
times $10^{37}$ erg/s the XLFs of field and GC-LMXBs are virtually
indistinguishable, hence we do not attempt a more detailed study
of luminosity distributions.

6. A case study for NGC 4365

The stacked source density profiles (Fig. 2) indicate that the ob-
served X-ray source excess in the galaxy outskirts cannot be ex-
plained only by the population of GC-LMXBs, but most likely
supernova kicked accreting NSs also play a notable role. To
separate the population of GC-LMXBs and supernova kicked
sources, GC-LMXBs must be identified at large galactocentric
radii. However, for most galaxies in our sample this is not fea-
sible due to the limitations of the available globular cluster data.
Although several galaxies in our sample have been observed by the Hubble Space Telescope (HST), these images do not cover their outskirts. Ground based observatories have larger field-of-view, but these images usually suffer from major incompleteness and foreground star contamination. An exception from this trend is NGC 4365, for which deep optical data is available, allowing to detect GCs even in its outskirts. Additionally, deep Chandra data is also available with a limiting luminosity of \( \sim 10^{37} \) erg/s. Therefore, we probe the X-ray populations of NGC 4365 as a case study.

NGC 4365 is a large elliptical galaxy with \( M_*=1.8 \times 10^{11} \) M\(_\odot\) and \( S_N = 3.95 \), which exhibits a notable source excess in the \((4 – 10)\, r_e\) region. The GC population of NGC 4365 has been studied as part of the SAGES Legacy Unifying Globulars and Galaxies Survey (SLUGGS). The galaxy and its outskirts have been observed in 8 pointings with the Advanced Camera for Surveys (ACS) onboard HST, which has been complemented with Subaru/S-Cam observations. Based on this combined data set, Blom et al. (2012) reported more than \( \sim 6000 \) GC candidates in and around NGC 4365. Beyond the central \( 0.5'\) \((\sim 1 r_e)\) the obtained list of GC candidates is complete to the turnover magnitude, additionally not significantly affected by contamination (Blom et al. 2012).

To build the list of GC candidates around NGC 4365, we relied on the publicly available SLUGGS\(^1\) data set, combining the HST and Subaru identifications together. If a GC candidate has been observed by both telescopes, we prioritized HST. We identified GC-LMXBs by cross-correlating the coordinates of detected X-ray sources following the method described in Zhang et al. (2011). The applied match radius was \( 0.5''\), which results in a total number of 104 X-ray sources residing in GCs within the study field. The estimated number of random matches is \( \sim 3 \). The 104 identified sources are designated as GC-LMXBs, whereas all the others are field sources.

In Fig. 5 we separately show the radial source density profiles of GC-LMXBs and CXB subtracted field sources, which are compared with the expected number of LMXBs based on the encased stellar mass and the average LMXB XLF (Sect. 3.1). In the \((4 – 10) r_e\) region 116 X-ray sources are detected (Table 2), which significantly exceed both the CXB prediction (44.6) and the expected number of LMXBs associated with the stellar light (11.3). Among the 116 sources, 25 sources are identified as GC-LMXBs, implying that \( 46.4 \pm 9.5 \) field X-ray sources are associated with the galaxy, which is \( \sim 3 \) times higher than the predicted LMXB number. Thus, we estimate that \( 35.1 \pm 9.5 \) sources could be associated with supernova kicked LMXBs.

Based on the above interpretation we conclude that 1) the source excess in the outskirts of NGC 4365 cannot be only attributed to GC-LMXBs, but presumably supernova kicked NS binaries also contribute; and 2) the importance of supernova kicked NS binaries is comparable to that of GC-LMXBs in a massive galaxy even with relatively high \( S_N \).

### 7. Discussion

#### 7.1. LMXBs associated with intracluster light

In galaxy clusters the stellar light is not only associated with luminous galaxies, but certain fraction (\( \sim 5 – 50\% \)) of the total optical cluster luminosity is associated with the intracluster light (ICL), which is bound to the cluster potential (e.g.,

\[^1\] http://sluggs.swin.edu.au/data.html
served source excess in the outskirts of galaxies correlate with a significant excess of X-ray sources in the (4 – 10)\,\text{Gyrs}, which resulted in 10 younger and 10 older systems. We divided to younger and older galaxies using median age of 6 the stellar age. In the view of these findings we investigate whether theob-evolution of the LMXB population with time is likely to play a role. In the view of these findings we investigate whether the observed source excess in the outskirts of galaxies correlates with the stellar age.

Following Zhang et al. (2012), the sample of 20 galaxies was divided to younger and older galaxies using median age of 6 Gyrs, which resulted in 10 younger and 10 older systems. We built stacked radial source density profiles for both sub-samples as described in Sect. 4.1 and depicted them in Fig. 7. Compared to the predicted LMXB level, both young and old galaxies have a significant excess of X-ray sources in the (4 – 10)\,\text{r_e} region. In young galaxies 199.8 sources are observed above the CXB level in the outer region, which is twice larger than the predicted number of LMXBs from the \(K_s\)-band light (66.8). For the old sub-sample we detect 409.6 sources above the CXB level, being a factor of 3.5 times more than the \(K_s\)-band prediction (91.3). Thus, the source excess appears to be somewhat more significant in old galaxies than in young ones. This result can be interpreted as the result of two combined effects. First, a strong correlation exists between the stellar age and the specific frequency of GCs (Zhang et al. 2012). Indeed, in our sample the median \(S_N\) is significantly higher for old galaxies (\(S_N = 4.64\)) than for younger ones (\(S_N = 1.56\)), implying that the frequency of GC-LMXBs is also notably higher for older galaxies in the outer regions. Second, if younger galaxies indeed have smaller populations of primordially formed LMXBs, there would also be fewer kicked sources in the outskirts. Note that the median stellar mass of the young and old sample is comparable (1.53\,\times\,10^{10} M_{\odot} and 1.47 \times 10^{10} M_{\odot}, respectively), hence the importance of supernova kicks should be comparable.

However, due to the correlation between the stellar age and \(S_N\), and the lack of complete GC catalogs (Sect. 6), the population of GC-LMXBs cannot be directly separated from supernova kicked neutron stars. Therefore, based on the present sample, it is not feasible to comprehensively study the frequency of supernova kicked sources as a function of the stellar age.

### 7.2. Stellar age dependence

In Zhang et al. (2012) we demonstrated that a correlation exists between the LMXB population and the stellar age of the host galaxy. Namely, the specific frequency of LMXBs is \(~ 50\%\) higher in older galaxies than in younger ones. We demonstrated that this excess could not be explained by only the fact that older galaxies have larger GC-LMXBs populations, but also intrinsic evolution of the LMXB population with time is likely to play a role. In the view of these findings we investigate whether the observed source excess in the outskirts of galaxies correlates with the stellar age.

Following Zhang et al. (2012), the sample of 20 galaxies was divided to younger and older galaxies using median age of 6 Gyrs, which resulted in 10 younger and 10 older systems. We built stacked radial source density profiles for both sub-samples as described in Sect. 4.1 and depicted them in Fig. 7. Compared to the predicted LMXB level, both young and old galaxies have a significant excess of X-ray sources in the (4 – 10)\,\text{r_e} region. In young galaxies 199.8 sources are observed above the CXB level in the outer region, which is twice larger than the predicted number of LMXBs from the \(K_s\)-band light (66.8). For the old sub-sample we detect 409.6 sources above the CXB level, being a factor of 3.5 times more than the \(K_s\)-band prediction (91.3). Thus, the source excess appears to be somewhat more significant in old galaxies than in young ones. This result can be interpreted as the result of two combined effects. First, a strong correlation exists between the stellar age and the specific frequency of GCs (Zhang et al. 2012). Indeed, in our sample the median \(S_N\) is significantly higher for old galaxies (\(S_N = 4.64\)) than for younger ones (\(S_N = 1.56\)), implying that the frequency of GC-LMXBs is also notably higher for older galaxies in the outer regions. Second, if younger galaxies indeed have smaller populations of primordially formed LMXBs, there would also be fewer kicked sources in the outskirts. Note that the median stellar mass of the young and old sample is comparable (1.53\,\times\,10^{10} M_{\odot} and 1.47 \times 10^{10} M_{\odot}, respectively), hence the importance of supernova kicks should be comparable.

### 7.3. Quantifying the number of excess sources

To statistically probe the origin of excess X-ray sources in the (4 – 10)\,r_e region, we characterized the LMXB specific frequency in each galaxy using:

\[
 f_{XLF} = \frac{N_X - N_{CXB}}{M_\star \times \int F(L)K_{LMXB}(L)\,dL},
\]

where \(N_X\) and \(N_{CXB}\) are the numbers of resolved X-ray sources and the predicted CXB sources. For each galaxy, these values agree with those listed for the outer regions in Table 2\,M_\star is the stellar mass in units of 10^{10} M_{\odot}, F(L) is the average differential XLF normalized to 10^{10} M_{\odot}, and \(K_{LMXB}(L)\) is the incompleteness function for LMXBs in each galaxy. Note that this formula is essentially identical with that introduced by Zhang et al. (2012).

According to equation (1), if the number of X-ray sources agrees with that predicted from the average XLF, we expect to
observe \( f_{\text{XLF}} = 1 \). However, for the studied 20 galaxies, we obtained the median value of \( f_{\text{XLF}} = 3.31 \) in the outer region, indicating a significant source excess. Assuming that the X-ray source excess originates from supernova kicked binaries and GC-LMXBs, we fit the data with a two parameter linear model:

\[
f_{\text{XLF}} = ax + bSN
\]

where \( M_* \) is the stellar mass in units of \( 10^{10} M_\odot \), and \( S_N \) is the globular cluster specific frequency. To find the best-fit values, we used \( \chi^2 \) minimization and obtained \( a = 0.081 \pm 0.025 \) and \( b = 0.60 \pm 0.12 \). The large \( \chi^2/d.o.f. = 104.9/18 \) implies notable scatter in the relation. Taking into account the median stellar mass \((M_*=1.3 \times 10^{11} M_\odot)\) and the median specific GC frequency \((S_N=2.0)\) of our sample, we find that (on average) the contribution of kicked binaries \((a \times M_*)\) and GC-LMXBs \((b \times S_N)\) is comparable. Thus, our statistical analysis confirms, that the excess X-ray sources have two different origins, namely from GC-LMXBs and supernova kicked binaries.

### 7.4. The role of supernova kicks

The fate of the kicked binary depends on the amplitude of the kick velocity with respect to the orbital velocity in the binary system \((v_{\text{orb}})\) and the escape velocity in the gravitational potential of the parent galaxy \((v_{\text{esc}})\). If the final velocity attained by the binary system \((v_{\text{sys}})\) exceeds the escape velocity, the binary will become unbound to its parent galaxy. On the other hand, if the kick velocity is too large with respect to the orbital velocity in the binary system, it will be destroyed by the kick \((e.g., \text{Brandt \& Podsiadlowski} 1995)\). Due to this selection effect, the average system velocities of LMXBs are expected to be smaller than for isolated neutron stars. \(\text{Brandt \& Podsiadlowski} 1995\) studied the effect of the supernova kick on the binary system. Assuming that the birth velocities of neutron stars are distributed according to \(\text{Lyne \& Lorimer} 1994\) with the mean value of \(450 \, \text{km/s}\), they concluded that LMXBs that remain bound after the supernova explosion have an average system velocity of \(v_{\text{sys}} = 180 \pm 80 \, \text{km/s}\). The typical escape velocities of our sample galaxies are in the range of \(v_{\text{esc}} = 250 \sim 1000 \, \text{km/s}\) \((\text{Scott et al.} 2009)\), larger than the average system velocity, therefore we should not expect that a significant fraction of LMXBs escape the parent galaxy, especially the more massive ones. Nevertheless, system velocities are comparable to the escape velocities, suggesting that natal kicks of the compact objects can significantly modify the spatial distribution of LMXBs in the galaxy, leading to its broadening as compared to the distribution of stars \(\text{Brandt \& Podsiadlowski} 1995\). However, this does not explain the observed dependence on the stellar mass. Indeed, assuming that the stellar mass is a proxy to the total gravitating mass, we should expect that the effect of kicks is stronger in the lower mass galaxies, opposite to what is observed.

However, it has been suggested that the birth velocity distribution of Galactic radio pulsar population has a bimodal structure, with the low velocity peak at \(\approx 90 \, \text{km/s}\) and the high velocity peak at \(\approx 500 \, \text{km/s}\). This hypothesis was tested by \(\text{Arzoumanian et al.} 2002\), who observed the new distribution of the natal kicks will result in the similarly bimodal velocity distribution of LMXBs \((e.g., \text{Repetto et al.} 2012)\). Thus, one may expect that the lower velocity component remains bound in any mass from our sample. The fate of the high velocity component, however, depends on the gravitational mass of the galaxy. In the higher mass galaxies it will remain bound but would be (much) broader distributed than stars, due to much larger average velocity, thus giving rise to the excess of X-ray sources in the galactic outskirts. In the case of the lower mass galaxies, with the escape velocity \(\sim 500 \, \text{km/s}\), the majority of the high velocity systems will escape the galaxy and no extended halo of LMXBs will appear.

The escaping binaries will travel to large distances in a relatively short time scale. Assuming a system velocity of \(v_{\text{sys}} = 200 \, \text{km/s}\) and a radial trajectory, we estimate that in 1 Gyr the binary will move from the host galaxy to a distance of \(\sim 200 \, \text{kpc}\). This value significantly exceeds the field-of-view of the presently studied \(\text{Chandra} (1995, \text{Repetto et al.} 2012)\). Thus, one may consider that during the supernova explosion, black holes and neutron stars receive the same momentum \((\text{rather than same kick velocity})\). In this model, the kick velocities of black holes are by a factor of \(\sim 5 \sim 10\) smaller that those received by the neutron stars, in accord with their mass ratios. Therefore black holes kicks would be insufficient to drive them out of even the lowest mass galaxies in our sample. This agrees with the fact, that the threshold luminosity above which the extended halo of X-ray sources vanishes, \((\sim 3 \sim 5) \cdot 10^{37} \, \text{erg/s}\), is close to the Eddington luminosity limit for the neutron star. It also suggests that the excess sources in the galactic outskirts with supernova kicked origins are neutron star binaries.

Above, we outlined a qualitative picture which may become a framework for a quantitative analysis. In order for this picture to be proven or falsified, realistic calculations need to be done, similar to the ones performed by \(\text{Brandt \& Podsiadlowski} 1995\), \(\text{Repetto et al.} 2012\). Results of such calculations can be compared with the observed radial source density profiles in galaxies of different masses. Such a comparison would also require detailed globular cluster information in order to remove contribution of globular cluster LMXBs. This, however, is beyond the scope of this paper.

### 8. Conclusion

In this paper, for the first time, we systematically explored the population of LMXBs in the outskirts of early-type galaxies. We studied a sample of 20 early-type galaxies based on archival \(\text{Chandra}\) data, which allowed us to perform a statistically significant study of the X-ray populations with a limiting luminosity of \(\sim 10^{37} \, \text{erg/s}\). Our results can be summarized as follows.

1. We demonstrated the existence of an excess X-ray source population in the outskirts of early-type galaxies. These sources form a halo of compact X-ray sources around galaxies extending out to at least \(\sim 10 \, \text{r}_e\) and probably much further. Their radial distribution is much broader that the distribution of the stellar light. The extended halo is comprised of sources with luminosity \(\leq 5 \cdot 10^{38} \, \text{erg/s}\), while the more luminous sources appear to follow the distribution of the stellar light without any notable excess at large radii. This suggests
that the majority of the excess sources are neutron star binaries.

2. Dividing the sample galaxies into four different groups based on their stellar mass and specific frequency of globular clusters, we found that the extended halo of compact sources is present in all groups except for the low-mass galaxies with low globular cluster content (small $S_N$).

3. We performed a case study of NGC 4365, for which galaxy deep optical (HST and Subaru) and X-ray data (Chandra) is available, allowing the identification of GC-LMXBs. In the $(4-10)r_e$ region we detected $60.1 \pm 10.8$ excess X-ray sources, out of which 25 are GC-LMXBs and 35.1 $\pm$ 9.5 are field sources which are presumably supernova kicked NS binaries.

4. Interpreting our findings, we proposed that the excess sources are comprised of two independent components: (i) dynamically formed sources in blue (metal poor) globular clusters, which are known to be distributed broader than the stellar light; (ii) primordial (field) neutron star LMXBs expelled from the main body of the galaxy due to kicks received during the supernova explosion.
