ABSTRACT

The first supernovae will soon be visible at the edge of the observable universe, revealing the birthplaces of Population III stars. With upcoming near-infrared missions, a broad analysis of the detectability of high-z supernovae is paramount. We combine cosmological and radiation transport simulations, instrument specifications, and survey strategies to create synthetic observations of primeval core-collapse, Type II and pair-instability supernovae with the James Webb Space Telescope (JWST). We show that a dedicated observational campaign with the JWST can detect up to $\sim 15$ pair-instability explosions, $\sim 300$ core-collapse supernovae, but less than one Type II explosion per year, depending on the Population III star formation history. Our synthetic survey also shows that $\approx 1 - 2 \times 10^2$ supernovae detections, depending on the accuracy of the classification, are sufficient to discriminate between Salpeter and flat mass distribution for high redshift stars with a confidence level greater than 99.5 per cent. We discuss how the purity of the sample affects our results and how supervised learning methods may help to discriminate between CC and PI SNe.

Key words: supernovae: general; cosmology: first stars; infrared: general

1 INTRODUCTION

The emergence of Population III (Pop III) stars ended the cosmic dark ages and began the production of elements heavier than lithium (Karlsson et al. 2013). But because Pop III stars have never been observed, their properties remain uncertain. Even detections of Pop III stars through strong gravitational lensing are very unlikely (Ryberg et al. 2013), so it may be decades before they are directly observed. The most viable strategy for probing the properties of the first stars is direct detection of their gamma-ray bursts (GRBs; Bromm & Loeb 2006, de Souza et al. 2013, Campisi et al. 2011, Nagakura et al. 2012, Mesler et al. 2014) and supernovae (SNe; Kasen et al. 2011, de Souza et al. 2013, Whalen et al. 2013b). Pop III SNe may soon be found in deep-field surveys by the James Webb Space Telescope (JWST) and all-sky surveys by Euclid (e.g., Whalen et al. 2013b, Johnson et al. 2013), providing unprecedented insights into cosmic evolution (Bromm 2013) and the properties of primordial mini-haloes (e.g., Whalen et al. 2008, Biffi & Maiolino 2013, de Souza et al. 2013a, 2014).

The JWST will be an infrared-optimized space telescope with four instruments, the Near-Infrared Camera (NIRCam), the Near-Infrared Spectrograph, the near-infrared Tunable Filter Imager and the Mid Infrared Instrument, with enough fuel for a 10-yr mission (Gardner et al. 2006). Our analysis is based on NIRCam photometry in the 0.6-5 $\mu$m bands, one of whose science goals is the exploration of the end of the dark ages. Complementary all-sky searches will also be possible with other NIR missions such as the Wide-Field Infrared Survey Telescope (WFIRST), the Wide-field Imaging Surveyor for High-redshift (WISH) and Euclid. Pop III SNe will also be visible in the radio at 21 cm to the Expanded Very Large Array (eVLA), eMERLIN and future radio facilities like the Square Kilometre Array (Meekin & Whalen 2013).

The quest for the first stars has been further motivated by the discovery of pair-instability (PI) SN candidates SN 2007bi at $z = 0.127$ (Gal-Yam et al. 2009; Young et al. 2010) and SN 2011fe at $z = 2.06$ (Cooke et al. 2012) and the pulsational pair-instability (PPI) SN candidate SN 1006+0216 at $z = 3.90$ (Cooke et al. 2012). These lower redshifts are less favorable to the formation of massive progenitors than in the early universe. There
is also evidence that some Pop III stars may be less massive than suggested by previous studies (Abel et al. 2002; Omukai & Palla 2003; Yoshida et al. 2004). Observationally, there is evidence of 15 - 50 $M_\odot$ Pop III stars in the fossil abundance record, the ashes of early SNe thought to be imprinted on ancient metal-poor stars (Beers & Christlieb 2005; Frebel et al. 2005; Cayrel et al. 2003; Y oshida et al. 2006). Observationally, there is evidence of 15 - 50 $M_\odot$ Pop III stars with masses below 50 $M_\odot$ (Beers & Christlieb 2005; Frebel et al. 2005; Cayrel et al. 2003; Y oshida et al. 2006). Observationally, there is evidence of 15 - 50 $M_\odot$ Pop III stars (Beers & Christlieb 2005; Frebel et al. 2005; Cayrel et al. 2003; Y oshida et al. 2006). Observationally, there is evidence of 15 - 50 $M_\odot$ Pop III stars (Beers & Christlieb 2005; Frebel et al. 2005; Cayrel et al. 2003; Y oshida et al. 2006). Observationally, there is evidence of 15 - 50 $M_\odot$ Pop III stars (Beers & Christlieb 2005; Frebel et al. 2005; Cayrel et al. 2003; Y oshida et al. 2006).

In Section 2, we discuss our cosmological assumptions for the Pop III IMF, and (iv) we present the first application of photometric classification techniques to study how well we can discriminate between different Pop III SNe types. The outline of the rest of this paper is as follows. In Section 2, we discuss our cosmological simulations, and in Section 3 we review our SN light curve (LC) calculations. Survey strategies and our synthetic observations are described in Section 4. In Section 5, we discuss future constraints on the Pop III IMF and our adopted statistics. In Section 5, we discuss how to identify each SN type and how this affects our results, and in Section 6 we present our conclusions.

2 COSMOLOGICAL SIMULATIONS

The SN rate is directly related to the cosmic star formation rate (SFR), which largely depends on the ability of primordial gas to cool and condense. Hydrogen molecules ($H_2$) are the primary coolant in primordial gas clouds, and they are sensitive to the soft ultraviolet background (UVB). The UVB in the $H_2$-disassociating Lyman-Werner (LB) bands delays star formation inside mini-haloes, and self-consistent cosmological simulations are required to properly account for this effect. We derive cosmic SFRs from a cosmological N-body, hydro and chemistry simulation (Johnson et al. 2013) done with a modified version (Schaye et al. 2010) of the smoothed-particle hydrodynamics (SPH) code GADGET (Springel et al. 2001, 2005). The modifications include line cooling in photoionization equilibrium for 11 elements (H, He, C, N, O, Ne, Mg, Si, S, Ca, Fe; Wiersma et al. 2009), prescriptions for SN mechanical feedback and metal enrichment, a non-equilibrium primordial chemistry network, and molecular cooling by $H_2$ and HD (Abel et al. 1997, Galli & Palla 1998, Yoshida et al. 2006, Maiolino et al. 2007). The transition from Pop III to Pop II/I SF occurs when the metallicity of the gas in the simulation, $Z$, exceeds the critical value $Z_{crit} = 10^{-4} Z_\odot$ (Omukai & Palla 2001; Bromm et al. 2001, Schneider et al. 2002, Mackey et al. 2003, Tornatore et al. 2007, Maiolino et al. 2010). The simulation starts from cosmological initial conditions and has a cubic volume 4 Mpc (comoving) on a side with periodic boundary conditions. It includes both dark matter (DM) and gas, with SPH gas and DM particle masses of $1.25 \times 10^4 M_\odot$ and $6.16 \times 10^3 M_\odot$, respectively. The simulation is launched with an equal number of SPH and DM particles, 684³. We adopt the WMAP7 cosmological parameters (Komatsu et al. 2009): $\Omega_m = 0.265$, $\Omega_b = 0.0448$, $\Omega_\Lambda = 0.735$, $H_0 = 71 km s^{-1} Mpc^{-1}$, and $\sigma_8 = 0.81$.

We assume a Salpeter IMF for Pop III stars (Salpeter 1955), with upper and lower limits $M_{upper} = 500 M_\odot$ and $M_{lower} = 21 M_\odot$, respectively (Bromm & Loeb 2004, Karlsson et al. 2008). The prescriptions for Pop III stellar evolution and chemical feedback track the enrichment of gas by the 11 elements listed above individually (Maiolino et al. 2007). We include a LW background from proximate sources and sources outside the simulation volume. The photodissociation rate due to this background is included in the reaction network throughout the run. In addition to the LW background, strong spatial and temporal variations in the LW flux can be produced locally by individual stellar sources (Dijkstra et al. 2008, Ahn et al. 2009), and this effect is included by summing the local LW flux contributions from all star particles. Self-shielding of $H_2$ to the LW background was implemented with shielding functions from (Wolcott-Green et al. 2011).

2.1 SN Rate

Since massive stars have cosmologically short lifetimes, $\approx 30 (M/8 M_\odot)^{-2.5}$ Myr, it is usually assumed that the SN rate, $\dot{n}_{SN}$, traces the cosmic SFR with redshift. This rate can be derived for a
particular mass range (and hence explosion type) from the IMF by

$$\dot{n}_{\text{SN}}(z) = SFR(z) \frac{\int_{M_{\text{min}}}^{M_{\text{max}}} \psi(M) dM}{\int_{15M_\odot}^{100M_\odot} M \psi(M) dM} \, \text{yr}^{-1}\text{Mpc}^{-3},$$

(1)

where $\psi(M)$ is the Pop III IMF, which we assume to have an either Salpeter ($dN/d\log M \propto M^{-1.35}$) or flat ($dN/d\log M \propto M$) slope. In reality, any IMF other than Salpeter is not entirely self-consistent, since mechanical feedback by SNe, metal enrichment, and the LW background can be dependent on the chosen IMF, and these in turn feed back into the SFR. But since Pop II SFRs are much higher than Pop III rates at $z < 15$, the contribution to feedback from Pop III stars is minor at later epochs. The overall SFR is therefore not very sensitive to the Pop III IMF, except perhaps at $z > 15$. Nevertheless, since most of the SNe occur at lower redshifts, this error is smaller than other astrophysical and numerical uncertainties and is thus subsumed in the wide range of parameters explored here.

The lower and upper limits for CC and PI SNe are $M_{\text{min}} = 15$ and $140 M_\odot$, and $M_{\text{max}} = 40$ and $260 M_\odot$, respectively. New results from Chatzopoulos & Wheeler (2013) show that Pop III stars down to $\sim 85 M_\odot$ may produce PI SNe if they are rapidly rotating, which could increase the PI SN rate by a factor of $\sim 4$. Our flat IMF is motivated by recent cosmological simulations of primordial star formation (Greif et al. 2011; Clark et al. 2011; Hirano et al. 2014).

The fraction of CC SNe that are Type IIn is not well determined but is assumed to be $10^{-3}$ of all CC SNe. This fraction is in agreement with Tanaka et al. (2012) and current constraints from the Robotic Optical Transient Search Experiment-IIIb (Quimby et al. 2013).

Fig. 1 shows $\dot{n}_{\text{SN}}$ from CC, Type IIn and PI SNe for different IMF and SFRs separately. Model SFR10 refers to the standard Pop III SFR, adopted in our previous work (DS13, Johnson et al. 2013), while model SFR10 is a more optimistic case with an Pop III SFR that is ten times higher, to account for numerical and astrophysical uncertainties. Our wide range of parameters aims to bracket the SFRs in the literature (Fig. 2, see also Fig. 3 from Whalen et al. 2013c). These rates come from numerical simulations (Campisi et al. 2011; Maio & Iannuzzi 2011; Wise et al. 2012; Hasegawa & Semelin 2013; Johnson et al. 2013a; Muratov et al. 2013; Pawlik et al. 2013; Xu et al. 2013; see Tornatore et al. 2007; Trenti & Stiavelli 2009 for other SFRs that fall within the range shown here), long-duration GRB rates (Ishida et al. 2011; Robertson & Ellis 2012) and UV-selected galaxies (Robertson et al. 2010). The rates predicted by both observations and simulations vary by about two orders of magnitude from $z \approx 10 - 25$.

The Pop III SFRs in most of the models are taken from those of a few protogalaxies in their simulation volumes and are therefore subject to small box statistics. At high redshift, galactic halos are rare and correspond to large peaks in the Gaussian probability distribution of initial fluctuations (Barkana & Loeb 2004). In simulations, periodic boundary conditions are usually assumed, thereby forcing the mean density of the box to be the cosmic mean density. This excludes density modes with wavelengths longer than the box size (4 Mpc in our case) from the simulations and results in an underestimate of the mean number of rare, biased halos. Accounting for these missing modes (Barkana & Loeb 2004), we estimate that the true SFR at $z = 7$ (20) could be larger by a factor of $\sim 1.3$ (7) if star formation is dominated by atomically cooled haloes, or a factor of $\sim 1.1$ (2) if star-formation is dominated by haloes cooled by $H_2$. The simulations also include a variety of feedback processes that lead to a wide range of evolution in stellar populations over redshift.

3 SN LC MODELS

The SN spectra in our study are calculated in three steps. First, the Pop III star is evolved from the zero-age main sequence to central collapse and then explosion in the one-dimensional (1D) KEPLER stellar evolution code (Weaver et al. 1978; Woosley et al. 2002). Nuclear burning is calculated with a 19-isotope network until oxygen depletion in the core, and with a 128-isotope quasi-equilibrium network thereafter. The KEPLER simulation is halted after the end of explosive burning, when the shock is still deep inside the star. The blast profile, surrounding star, and stellar envelope (a low-density $r^{-2}$ wind profile) are then mapped onto a 1D spherical grid in the Los Alamos RAGE code (Gittings et al. 2008) and evolved through shock breakout from the star and subsequent expansion into the intergalactic medium (IGM). Finally, RAGE profiles are post processed with the Los Alamos SPECTRUM code (Frey et al. 2013) and OPLIB opacities (Magee et al. 1995) to obtain spectra at 14899 wavelengths. We summarize the properties of our SNe in Table 1.

PI SNe We consider 150, 175, 200, 225, and 250 $M_\odot$ PI SN progenitors at zero-metallicity (z-series) and $Z = 10^{-4} Z_\odot$ (u-series) (Joggerst & Whalen 2011; Whalen et al. 2013c). The u-series stars die as red supergiants and the z-series stars die as compact blue giants. It is generally thought that most stars in this mass range die as red supergiants due to convective mixing over their lives, even at zero metallicity. The onset of the PI and explosion is an emergent feature of the stellar evolution model and does not have to be artificially triggered. PI SNe exhibit little internal mixing that would break the spherical symmetry of the star during the explosion and are generally well-described by 1D models. They make up to 40

4 http://rdc.llnl.gov
High-z initial mass function

$M_{\odot}$ of $^{56}\text{Ni}$ and release up to $10^{53}$ erg, which powers the LC at intermediate to late times. We evolve these explosions out to 3 yrs because they can be bright out to these times, in part because of the longer radiation diffusion timescales in their massive ejecta. The red supergiants and blue giants in our grid of models bracket the range of structures expected for these stars. Their actual structures, and hence explosion LCs, may be intermediate to those here.

CC SNe The CC SNe in our study are $15 - 40 M_{\odot}$, with explosion energies, $E$, of 0.6, 1.2, and $2.4 \times 10^{51}$ erg (the B, D, and G models, respectively). They have the same metallicities as our PI SN models and also die as red supergiants ($z$-series) and compact blue giants ($u$-series), a total of 18 models. Unlike the PI SNe described above, these explosions must be artificially triggered with linear momentum pistons in KEPLER. Before mapping them to RAGE, these SNe are evolved from the end of explosive burning until just before shock breakout in two dimensions (2D) in the CASTRO adaptive mesh refinement (AMR) code (Almgren et al. 2010). We do this to capture the violent mixing between elemental shells in the star before the SN shock ruptures its surface, as described in Joggerst et al. (2010). These 2D profiles are then averaged in angle, mapped into RAGE, and evolved through shock breakout out to 4 months.

In Fig. 3, we show an example of CC, Type IIn, and PI SN spectral evolution from breakout to 100 days in the rest frame. The evolution of the PI and CC SN SEDs over time is mainly governed by two processes: (i) the fireball expands and cools, and its spectral cutoff advances to longer wavelengths; (ii) the ejecta and envelope, which were ionized by the breakout radiation pulse, begin to recombine and absorb photons at the high energy end of the spectrum, as evidenced by the flux that is blanketed by lines at the short-wavelength limit of the spectrum. At later times, flux at longer wavelengths slowly rises due to the expansion of the surface area of the photosphere. The SEDs are blue at earlier times and become redder at later times as the expanding blast cools. In the Type IIn explosion, the shock driven by the ejecta through the shell causes the jump in luminosity after $\sim 30$ days. The magnitude of the jump depends on the density of the shell, with diffuse shells allowing more radiation to pass through them. A comparison between the SED evolution for different SN types in the rest-frame and at redshift 6 are shown in
For higher redshifts the overall SED is shifted to redder bands allowing a first estimation of the redshift of the source by dropout techniques (Fig. 5).

In Fig. 5 we show LCs in the rest frame and at redshifts 6, 10 and 15 for comparison. The CC SNe exhibit plateaus in the optical bands in the rest frame. But high-redshift Type IIP (CC) SNe do not exhibit plateaus in the NIR because emission in the much bluer bands of origin in the rest frame rapidly declines due to the onset of line opacity at early times in the fireball (compare Fig. 4 with Fig. 7 from Kasen & Woosley 2009), in which the U band flux falls off rapidly in comparison to the plateaus in the I, R and V band fluxes (see also Pan et al. 2012)). The absence of a plateau in the bluer bands in the rest frame of high-z CC SNe is key to their detection in the NIR today. Otherwise, they might not be recognizable as transients.

4 SYNTHETIC OBSERVATIONS

We generate synthetic LCs with a modified version of the Supernova ANALyst (SNANA; Kessler et al. 2009) LC simulator, as in DS13. It is a complete package for SN LC analysis, and accepts astrophysical characteristics of the source, IGM (see appendix A), and survey parameters as inputs. The SNe are specified by their IMF as described in Section 2.1. Other physical elements like IGM filtering and the primary refer-

ence star, which defines the magnitude system to be used, are convolved with the specific filter transmissions through the construction of k-correction tables. Such tables transform the fluxes from source frame to the observer frame, on top of which extinction by other physical elements like IGM filtering and the primary reference star, which defines the magnitude system to be used, are convolved with the specific filter transmissions through the construction of k-correction tables. Such tables transform the fluxes from source frame to the observer frame, on top of which extinction by the Milky Way is applied using full-sky dust maps (Schlegel et al. 1998). We also include telescope specifications such as CCD characteristics, field of view (FOV), point spread function (PSF) and pixel scale (Table D). AB magnitudes are used for all the simulations presented here.

The instrument characteristics in our synthetic observations are based on NIRCam (appendix D; see also Gardner et al. 2006). All simulations assume individual integrations of $10^3$ s, which can sometimes be co-added to create longer exposures. The two strategies tested here are the same as those in DS13 (Table 2):

- **Strategy 1 (str1)** One pointing per year for each of the six reddest filters in NIRCam (F115W-F444W), to maximize our ability to identify high-redshift sources from non-detections in the bluest filters (dropouts).

- **Strategy 2 (str2)** Three pointings per year separated by two-month gaps in filters F150W and F444W, to maximize the number of SN detections.

Both strategies assume a 5 yr survey time, with $\sim$ 730 hours of telescope time per year and a sky coverage of 0.06 per cent. Finding at least a few detections near the LC peak is crucial to our goal of identifying these events as transients and photometrically categorizing them by SN type (e.g., Ishida & de Souza 2013). Therefore, for an event to be labelled a SN we require its detection at a minimum of one epoch before and after maximum brightness. We also require its detection at three epochs in at least one filter above the background limit and selection cuts on signal to noise (S/N) ratio $\geq 2$ (cut1) and $\geq 3$ (cut2) in at least one filter.

In Fig. 5 we show examples of LCs obtained by both strategies. The error bars denote the uncertainties in the magnitude measurements due to the background on the sky, photon statistics and instrument calibration. The errors are summed in quadrature and considered over an effective aperture based on PSF fitting, which we take to be Gaussian (see appendix C). From this figure, we conclude that detecting a SN in the six reddest filters indicates an event at moderate redshift, $z \lesssim 10$, while a detection in only the four reddest filters suggests a SN at $z \gtrsim 15$.

Fig. 7 shows the number of detections in comparison to the total number of SNe in the field. A few important conclusions can be drawn by inspecting the histograms:

- **str2** clearly optimizes the detection rate of all SN types for cut1 for both SFR1 and SFR10 (using the same amount of time), but at the cost of getting information in a smaller number of filters. However, str1 seems to be more effective at detecting the higher quality LCs imposed by cut2. This is mainly due to the larger number of filters in this strategy, which increases the likelihood of finding a brighter event in at least one filter (the exact number of detections are presented later in Section 5 and Appendix B).

- The relative number of SNe detected of each type is strongly correlated with the underlying IMF, and therefore might be used as a probe of the Pop III IMF, as discussed later in this article. For instance, CC detections increase by almost an order of magnitude from the flat to the Salpeter IMF because the mass distribution of the latter is biased toward less massive stars.

- Given a fixed amount of telescope time, changing the observation strategy might increase the number of detections.

To be more quantitative, for the most optimistic case (SFR10+cut2) we obtain $39 \pm 9$ (67 $\pm$ 13) PI SNe, and $535 \pm 33$ (1451 $\pm$ 70) CC SNe with str1 (str2) for the Salpeter IMF. We find $76 \pm 12$ (124 $\pm$ 17) PI SNe and $61 \pm 10$ (159 $\pm$ 22) CC SNe with str1 (str2) for the flat IMF. For Type Ibn SNe, the detection rate is negligible, with $\sim 1$ event every 10 yr in the most optimistic case, so we do not bin them here. This is a clear indication that JWST can observe a large number of Pop III SNe, particularly CC SNe. Once potential candidates are detected, the brightest sources will be suitable for more detailed spectroscopic followup, which can place strong limits on their metal content.

Whilst the PI SNe are brighter enough to be detected by JWST at redshifts as high as $z \sim 25$, the scarcity of such events makes their detection at the lowest redshifts more tangible. Our results

Note that we are zooming the SED, and few features might be missing in current plot, such as P-Cygni profiles in CC SNe. We refer to the original articles Whalen et al. (2013a,b,c,d) for a deep discussion of physical properties of each particular SN.

Our observation fields were centered around Hubble Ultra Deep Field (Beckwith et al. 2006).

Note that $\sim 10^3$ s is the limit for individual exposures due to cosmic ray contamination in the line of sight (Gardner et al. 2006).

NIRCam consists of two fully redundant optical trails, which allows simultaneous observations of the same FOV in 2 filters, one in lower (F070W-F200W), and the other in higher (F277W-F444W) wavelengths Gardner et al. (2006). Taking advantage of this feature, our strategies were built so that each pointing gathers observations in 2 filters through 100s.

All numbers are an average over 200 simulations.

For low-metallicity objects, the ratio of oxygen lines to Balmer lines, such as [OIII]/H$\alpha$, provides a linear measurement of metallicity.
5 PROBING THE PRIMORDIAL IMF

The ultimate goal of a complete theory of primordial star formation is to predict the Pop III IMF from first principles (Bromm 2013). Finding the first cosmic explosions would be a leap forward in our understanding of the basic processes behind the formation of the first stars. Since each SN type to some degree encodes the mass of its progenitors, their relative rates can place firm constraints on the Pop III IMF.

But inferring the nature of a progenitor from its SN may not be simple. Even the progenitors of well-studied Type Ia SNe are not fully understood (Hillebrandt & Niemeyer 2000, Wang & Han 2012), although it is generally believed that they fall into one of two types: single-degenerate and double-degenerate mergers (Maoz et al. 2013). Techniques like integral field spectroscopy have been used to obtain both spatial and spectral information on the explosion site, allowing the identification of the parent population of the star. While many stellar evolution models have been proposed to characterize the progenitor stars, these predictions are still poorly supported by observations (Kuncarayakti et al. 2013). Given the aforementioned sources of uncertainties, instead of reconstructing the Pop III IMF directly from the data, we seek the answer to a more straightforward question: is it possible to distinguish a Salpeter IMF from a flat IMF by counting the relative observed rates of CC and PI SNe? In other words, we want to test the following null \( H_0 \) and alternative hypotheses \( H_a \):

\[
\begin{align*}
H_0 & : \text{The relative observed frequencies of CC and PI SNe are independent of the IMF.} \\
H_a & : \text{The relative observed frequencies of CC and PI SNe are not independent of the IMF.}
\end{align*}
\]

The CC and PI SNe can be treated as categorical variables and their degree of dependence on the IMF can be investigated using categorical data is composed of variables that can be separated into mutually exclusive classes, but there is no intrinsic ordering to the categories.
Figure 5. Light-curve evolution of the z40G CC SN (blue solid line), the a02 Type IIn (green dashed line), and the u200 PI SN (red long-dashed line). LCs are at 10 pc, z = 6, 10 and 15.

Table 1. Properties of CC (Whalen et al. 2013c), IIn (Whalen et al. 2013d) and PI SNe (Whalen et al. 2013a,b) explosions: progenitor mass (\(M_\star\)), SN energy (E), and metallicity (Z). The Type IIn explosions all have a progenitor mass of 40 \(M_\odot\), but different shell masses and thus luminosities.
the formalism of contingency tables (Becker et al. 1996). A 2 × 2 contingency table is a way of visualizing the dependence between two categorical variables (columns) and a given factor (rows). Examples of such tables for three of the scenarios in Fig 4 are shown in Tables 3, 4, and 5. To measure the degree of correlation between them, we use the χ² test of independence.

Let O_{ij} be the original contingency table and E_{ij} be the one we would expect to measure if the categorical variables were independent. The latter is constructed by multiplying the sum of rows (R_i) and columns (C_j) of O_{ij} and then dividing by the total number of observations (N), E_{ij} = R_i × C_j / N. In the tables described above, the E_{ij} for each case is shown in parentheses. We reject H_0 if the p-value of the following χ² test is below a given significance level α,

$$\chi^2 = \sum_{i,j} \frac{(O_{ij} - E_{ij})^2}{E_{ij}},$$

where typical values for alpha are 0.01 or 0.05, representing 99 and 95 per cent confidence levels, respectively. For instance, the χ² test for Table 3 is given by

$$\chi^2 = \frac{(339 - 449.81)^2}{449.81} + \frac{(9312 - 9201.19)^2}{9201.19} \approx 1005.$$  

In order to emulate a realistic scenario, we compared each of the synthetic observations with a basis model. Thus, the first row of all the tables are equal (representing our basis model) while the second row represents the observed sample for each case. Our fiducial model is composed of the total number of SNe expected to appear in the JWST survey area, assuming a Salpeter IMF and SFR10.

Figure 6. SEDs of CC, Type IIn and PI SNe as they would be observed by the JWST NIRCam in our two observational strategies. We show each LC at z = 6 (left panel), 10 (central panel) and 15 (right panel). The y-axis is the observed magnitude and the x-axis is the time in the observer frame. The high-redshift events vanish from the bluest filters and their LCs last longer due to time dilation. The grey panels represent the filters not used by a specific strategy, and in the blank panels there were no detections.
Tables 3 and 4 show the contingency tables for observed samples with flat and Salpeter IMFs, respectively. Both tables assume SFR10 and cut1 (for the others, see appendix B). An observed sample whose IMF is flat is easily seen not to be Salpeter with a 99.95 per cent confidence level because $\chi^2 \approx 1005$, with a $p$-value $\lesssim 0.0005$. Furthermore, the observed sample whose IMF is Salpeter is not wrongly rejected due to observational bias, with $\chi^2 = 2.79$ and a $p$-value $= 0.095$. From Tables B1-B3, we see that the flat IMF is systematically rejected in all scenarios, showing high values of $\chi^2$: 365.5 (a $p$-value $\lesssim 0.0005$ for str2+cut2), 893.3 (a $p$-value $\lesssim 0.0005$) for str1+cut1, and 755.6 (a $p$-value $\lesssim 0.0005$) for str1+cut2.

In Tables B4-B6, we show the comparison with an observed sample generated from a Salpeter IMF. All values of $\chi^2$ are lower than for the flat IMF, indicating a better agreement with $H_0$. Thus, we can already conclude that the $\chi^2$ analysis is able to indicate the most likely IMF between two scenarios.

More insights can be gained from the relative risk (RR; Zhang & Yu 1998). If the samples are drawn from the same IMF, RR approaches 1, while it diverges from 1 when the samples are from two divergent IMFs. In other words, RR measures the probability of a certain event occurring in one group versus another. Therefore all numbers between brackets, representing the $E_{ij}$ table, are constructed in such a way that $RR \approx 1$. Hence, our method determines if deviations from $RR = 1$ are driven by random fluctuations or by some intrinsic effect of the underlying IMF. An interesting effect arising from the RR analysis is the Malmquist bias, which leads to the preferential detection of intrinsically brighter objects. Comparing Tables 4 and B4, the RR for PI SNe changes from 0.796 to 0.433 merely by changing the S/N requirement. This means that the probability of observing a PI SN is almost twice as high when cut2 is applied instead of cut1. This happens because the more stringent the detection limit, the more biased our sample will be towards brighter objects.

While the $\chi^2$ analysis is useful for deciding which IMF better fits the data, it is also important for determining if the observed and theoretical samples are drawn from the same IMF in a self-consistent manner. For instance, because of the low number of events from str1, the $p$-value analysis per se wrongly rejects the Salpeter IMF, finding $p$-values $< 0.05$ (Tables B5 and B6). In other words, even if the fiducial and observed models are drawn from the same IMF, poor statistics may cause a bias in our conclusion. Thus, determining the proper size of a sample is a crucial step for experiment design, and it constitutes a branch in statistics known as power analysis that we discuss in greater detail below.

5.1 Sample size

Once we are convinced the above procedure is satisfactory for our purposes, we still need to optimize the use of telescope resources in order to design a realistic survey. Therefore, it is important to determine the minimum sample size necessary to measure a desired effect or to estimate how much should we trust a particular result, given the sample size allowed by observational constraints.
Otherwise, even if the survey is performed perfectly and analyzed properly, wrong conclusions could still be made due to the lack of statistical power ($P$). $P$ can be understood to be the probability of rejecting $H_0$ when $H_a$ is true. In our case, it represents the ability to detect true deviations from the Salpeter IMF in the observed sample. Therefore, while $\alpha$ represents the probability that $H_0$ will be rejected when it is actually true (a wrong decision), $P$ quantifies the likelihood of rejecting $H_0$ when it is actually false (a correct decision).

$P$ depends on the effect size ($W$), confidence level, $\alpha$, and number of detections, $N$. $W$ determines the deviation from $H_0$ that one would expect to detect. The number increases with the degree of discrepancy between the distribution of $H_a$ and $H_0$.

\[
W = \sqrt{\sum_{i=1}^{2} \frac{(P_{0i} - P_{Ei})^2}{P_{Ei}}},
\]

where $P_{0i}$ and $P_{Ei}$ are the proportions (counts divided by total number of observations) in each cell for the $O_{ij}$ and $E_{ij}$ contingency tables, respectively. It can be written in terms of $\chi^2$ as $W = \sqrt{\chi^2/N}$. For our basis model shown in Table S in the near future given a reasonable amount of telescope time.

While it follows a noncentral $\chi^2$ distribution for noncentrality parameter $\lambda = 20 \times 0.44$ (20 detections, $W = 0.44$) and $\lambda = 50 \times 0.44$ (50 detections, $W = 0.44$) respectively. The vertical dotted grey line represents the $\chi^2$ value with a probability of 0.05 under $H_0$. If we get a $\chi^2$ statistic to the left of the line we conclude that it came from the $H_0$ and if it is to the right of the line then we conclude it came from $H_a$. The area under the alternative distribution to the right of the line represents the power of the test. Thus, the higher the number of observations, more straightforward is to discriminate $H_a$ from $H_0$. Which in our case represents the ability to conclude if the distribution is consistent with Salpeter of not.

In Fig. 9 we show a graphical representation of $P$. The shaded red area on the left of the grey-dashed line at $\chi^2 = 3.84$ represents 99.5 per cent confidence level for the $\chi^2$. In this context, $P$ is the area under $\chi^2(x, \lambda)$ falling on the right side of the grey-dashed line. Therefore the rightmost the $\chi^2(x, \lambda)$ distribution for $H_a$ is, the easier it will be to discriminate it from the $\chi^2$ distribution. Higher values of $\lambda$ implies higher deviations from $\chi^2$. Hence, $P$ grows in the same way as the number of detections.

In Fig. 9 we show that $\sim 10^5$ SN detections are necessary to distinguish between a Salpeter and a flat IMF with the $\chi^2$ test. It is important to note that the former number represents the number of SNe properly classified within their respective categories, not the total number of SNe appearing in the FOV. This is a remarkable result because it shows that the Pop III IMF could be unveiled in the near future given a reasonable amount of telescope time.

Finally, the methodology suggested here is broad enough to determine which of two IMF better describe the data. We use the Salpeter and flat IMF as a benchmark of the test since these are two physically motivated models. Furthermore our methodology defines a straightforward way to determine the minimum sample requirements to achieve a reliable result.

6 SUPERNOVA TYPING

The analysis delineated in the last section implicitly assumes that all SNe have been properly classified into their own groups. Nevertheless, once we have identified a Pop III SNe, we must classify them into PISN/CC events and provide some estimate of the level of contamination. These are far from trivial tasks and a detailed study of all nuances underlying the SNe photometric classification (Ishida & de Souza 2013) demands a separate work. However, we describe below how such problems can be tackled, demonstrating once more the potential of Pop III synthetic surveys as test grounds for future analysis.

Distinguishing between PI and CC SNe would be fairly straightforward if one can measure their redshift. In rest-frame, NIR PISN light curves last significantly longer than CC ones due to longer radiation diffusion timescales in their more massive ejecta. Although, before performing a time consuming spectroscopic follow-up on such faint targets, it is wise to develop an optimized strategy for photometric classification to identify potential candidates. This subject is already highly developed within the type Ia SN community (Kessler et al. 2010), and the existing approaches are usually divided in two classes: empirical (e.g., Newling et al. 2011; Richards et al. 2012; Karpenka et al. 2013, Ishida & de Souza 2013) and template fitting (e.g., Sullivan et al. 2006; Poznanski et al. 2007; Kuznetsova & Connolly 2007; Kunz et al. 2007; Sako et al. 2008).

Rodney & Tonry 2009, Sako et al. 2011 methods. The former uses magnitudes and/or fluxes of a spectroscopically measured sample for training the method, which is then applied to the photometric sample. The latter, try to find spectral template and redshift which best fit the photometric observations using a library of well know observational or synthetic spectra.

Since we have not yet observed any Pop III stars, which could in principle be used as a training sample, the best we can do is to base our analysis on synthetic LCs in order to estimate our potential power in discriminating between CC and PI SNe. Following the procedure suggested by Ishida & de Souza 2013, see appendix [E1], we present in Fig. 10 the projections of CC and PISN LCs into a 2-dimensional space obtained from Kernel Principal Component Analysis (KPCA). Each point represents a LC observed in filters F200W, F277W, F356W and F444W with a cadence of two months in each filter. The dispersion of the projected points are mainly caused by the intrinsic variance of different SN models, S/N and redshift. Each SN type in the figure is identified by colour, while the marker style indicates if an object was correctly classified or not by a cross-validation procedure using the k-nearest neighbor predictor within a Leave One Out (LOO) cross-validation procedure (appendix [E3]).

In the context of this work, each iteration of the LOO algorithm can be interpreted as an attempt to classify a new unknown object given the synthetic data set. Consequently, the cross-validation can be understood as an indicative of the power of the method in discriminating between each class of SN. Nevertheless a more realistic prediction requires the application of the trained classifier to a new set of LCs whose classes are unknown. Furthermore, we should carry an exhaustive study of the observational cadency, data quality, expected amount of spectroscopic confirmed and photometric objects of each type, LC fitting method, number of used photometric bands, and so on. Such analysis is out of the scope of the present work, but planned to be carried in the future.

The confusion matrix for the objects present in Fig. 10 is given in Table 6 representing the number of SN correctly (diagonal) and incorrectly (off-diagonal) classified during the cross-validation. For this example case, the method achieve an accuracy of ~ 76.3 per cent. Assuming that the real SN will not be very different from our simulations, the results suggests an approximate upper limit for our ability to correctly discriminate between these objects. It has direct implications in the analysis developed in Section 5.1, which implicitly assumes an error-free classification of the LCs.

In other words, standard power analysis does not take into account the reliability (\(\mathcal{R}\)) of the measurement. According to Kanyongo et al. 2007, a \(\mathcal{R} \neq 1\) affects \(P\) by indirectly changing \(W\) as follows

\[
W_{\text{obs}} = W\sqrt{\mathcal{R}},
\]

where \(\mathcal{R}\) is defined by the ratio of true variance (\(\sigma_{\text{true}}^2\)) to observed variance (\(\sigma_{\text{obs}}^2\))

\[
\mathcal{R} = \frac{\sigma_{\text{true}}^2}{\sigma_{\text{obs}}^2}.
\]

By changing \(W\), we increase the number of observed objects necessary to reach the same \(P\). For instance, considering \(\mathcal{R} = 0.7\) (0.6) would increase the number of objects necessary to reach a power of 99.5 per cent to ~ 150(180) SN. Therefore considering a feasible

- Number of correct classifications: 302+576 = 878
- Number of incorrect classifications: 129+144 = 273
- Accuracy: $\frac{878}{878+273} \approx 0.763$

7 CONCLUSIONS

We have created the first, detailed synthetic observations of high-$z$ SNe. With cosmological and radiation hydrodynamics simulations, together with detailed models of instrument properties and IGM absorption, we show that a viable survey strategy could detect up to $\sim 300$ CC and $\sim 15$ PI SNe per year. We also find that information from multiple filters is crucial for detecting and distinguishing high-$z$ SN candidates from low-$z$ events with dropout techniques. Our study also shows that the low rates of Type IIn SNe will likely prevent their detection in deep-field surveys, and all-sky missions such as Euclid will be better suited for this task. Survey strategies for Pop III SNe in all-sky missions such as Euclid, WFIRST and WISH will be examined in future work.

New calculations now show that additional SN types not considered here will also be visible at high redshifts. Whalen et al. (2014) have now shown that 100 - 140 $M_\odot$ PPI SNe will be visible to JWST at $z \sim 10 - 20$, and, depending on the Pop III IMF, may be as numerous as PI SNe (see also Woosley et al. 2007). Hypernovae, the highly energetic and asymmetric explosions of 40 - 60 $M_\odot$ stars, will likewise be visible out to $z \sim 10 - 15$ (Smidt et al. 2014), and detection limits in redshift for 85 - 135 $M_\odot$ PI SNe are now being investigated (Whalen et al. 2013). These additional SN classes will be considered in future mock surveys.

Our synthetic survey allows us to perform the first comprehensive statistical study on the feasibility of using ancient cosmic explosions to constrain the stellar IMF in the early Universe by counting the relative detection rates of CC and PI SNe. Given the realism with which we simulate the observing process, our synthetic sample may be easily used to calibrate photometric classification techniques. Using the formalism of contingency tables together with well-established $\chi^2$ statistics, we show that at least $10^2$ SNe detections will be necessary to distinguish between Salpeter and flat IMFs with a 99.5 per cent confidence level.

We show that machine learning techniques constitute a promising tool to discern between CC and PI SNe only relying on photometric information. Even if the accuracy of our classification is as low as 60 per cent, we show that $\lesssim 200$ observations are enough to discriminate between the two IMFs. This represents a leap forward in high-redshift SN studies, which may shed light on the long-standing puzzle of the primordial IMF.

We thank Joseph Smidt for providing part of the data present in Fig. 1. RSS thanks MPA for the hospitality during the preparation of this work.

APPENDIX A: IGM ABSORPTION

The spectra of events at $z > 6$ blueward of 1216(1 + $z$)Å (Gunn & Peterson 1965; Mesinger et al. 2004) are heavily ab-
sorbed by the neutral IGM (Ciardi et al. 2012). The contribution to the optical depth \( \tau_{\text{IGM}} \) comes mainly from damped Ly\( \alpha \) absorbers (DLAs), Lyman Limit Systems (LLSs), optically thin systems and resonance line scattering by the Ly\( \alpha \) forest along the line of sight. We account for absorption by the neutral IGM at high-\( z \) by multiplying each SED by the IGM transmission function for the source redshift. The observed spectrum \( f_{\lambda, \text{obs}} \) after IGM attenuation is

\[
f_{\lambda, \text{obs}} = f_{\lambda} e^{-\tau_{\text{IGM}}}. \tag{A1}
\]

We compute transmission through the IGM with the JAVA code \textsc{igmtransmission} (Harrison et al. 2011). Our model uses a Monte-Carlo approach to distribute LLSs chosen from a redshift distribution \( dN/dz \) and an optical depth distribution \( dN/d\tau_{L} \), averaged over IGM transmission along many lines of sight (Meiksin 2003).

The contribution from optically thin systems is

\[
\tau_{L}^{\text{IGM}} = 0.07553(1 + z_{L})^{4.4} \left[ \frac{1}{(1+z_{L})^{2}} - \frac{1}{(1+z)^{2}} \right], \tag{A2}
\]

where \( z_{L} = \lambda/\lambda_{L} - 1 \) and \( \lambda_{L} = 912 \text{ Å} \). The contribution due to the optically thick \( (\tau_{L} > 1) \) LLSs is

\[
\tau_{L}^{\text{LLS}} = \int_{z_{L}}^{\infty} dz' \int_{1}^{\infty} d\tau_{L} \frac{\partial^{2} N}{\partial \tau_{L} \partial z'} \left[ 1 - \exp \left( -\tau_{L} \left( \frac{1 + z_{L}}{1 + z'} \right)^{3} \right) \right], \tag{A3}
\]

where \( \frac{\partial^{2} N}{\partial \tau_{L} \partial z'} \) is the number of absorbers along the line of sight per unit redshift interval per unit optical depth of the system.

The spatial distribution of the LLSs is (Meiksin 2003)

\[
\frac{dN}{dz} = N_{0} (1 + z)^{\gamma}, \tag{A4}
\]

where \( N_{0} = 0.25 \) and \( \gamma = 1.5 \). The optical depth distribution is

\[
\frac{dN}{d\tau_{L}} \propto \tau_{L}^{-\beta}, \tag{A5}
\]

where \( \beta = 1.5 \).

**APPENDIX B: CONTINGENCY TABLES**

Contingency tables are used to analyse the relationship between two or more categorical variables. It is the categorical equivalent of the scatter plot used to analyse the relationship between two continuous variables. A categorical variable is one that has two or more classes, but there is no intrinsic ordering between them. For example, gender is a categorical variable having two possible classes (male and female), and there is no intrinsic ordering to the categories. Hence, the SN types can be treated as categorical variables since they are mutually exclusive.

We can measure the association between the occurrence of a CC or PI SN and the IMF through their RR. In Table B1, we have an example of RR calculation for the fiducial model and the case with a flat IMF, SFR10, cut2 and str2. The RR in this case is 2.894 for CC SNe and 0.053 for PI SNe, meaning that a Salpeter IMF is \sim 3 times more likely to produce a CC event than in the flat IMF.

**APPENDIX C: NOISE CALCULATION**

This section briefly describes how the uncertainties in measured fluxes and magnitudes are built (error bars in Fig. 6). A more in-depth discussion and example calculation can be found in the SNANA Manual, section 4.12.

Consider the simulation of the observation of an event in a filter at one epoch. The SED describes the evolution of the spectrum of this event over time in the frame of the SN. This information is then redshifted into the observer frame, taking into account cosmological dimming, absorption by the IGM, Milky Way extinction, the collection area of the telescope mirror, total exposure time, etc. The product of this calculation is the AB magnitude (m) of the SN, minus the errors due to the observing process. In order to evaluate these errors and account for them into our synthetic observations, we need to incorporate at least 3 important sources of uncertainty:

- the determination of the signal itself, \sigma_{sig};
- sky background, \sigma_{sky};
- calibration process (determination of the zero point), \sigma_{ZPT}.

The measured source signal can be expressed in terms of the number of photoelectrons generated in the CCD, \text{N}_{pe}. In this case, \sigma_{sig} = G^{-1} \sqrt{\text{N}_{pe}} in analog-to-digital-units (ADU), where \text{G} is the CCD gain (pe/ADU). The sky background error is given by \sigma_{sky} = \pm \sqrt{\text{A} \sigma_{sky}^2} where \text{A} is the PSF equivalent area, represented by a simple Gaussian of full-width-at-half-maximum \sigma_1 (A = 4\pi \sigma_1^2), and \sigma_{sky} is the measured uncertainty in sky brightness per pixel (ADU/pixel). The error coming from the zero point magnitude (\sigma_{ZPT}) encodes information about the atmospheric transparency and telescope aperture and efficiency, but does not depend on the signal from this particular object. Thus, the statistical error due to photon statistics is composed of \sigma_{sig}/F and \sigma_{sky}/F. These should be added in quadrature to \sigma_{ZPT}, which represents an additional statistical error coming from stellar calibration.

Finally, the uncertainty in flux determination (in ADU) is

APPENDIX E: SUPERNOVA PHOTOMETRIC CLASSIFICATION

E1 Kernel Principal Components Analysis

KPCA generalizes the standard PCA by first mapping the data into a higher dimensional feature space \( \mathbb{F} \):

\[
\Phi : \mathbb{R}^n \rightarrow \mathbb{F}
\]

\[
\Phi(x) \rightarrow \Phi(x),
\]

where \( \Phi \) is a nonlinear function and \( \mathbb{F} \) has arbitrary number of dimensions.

The covariance matrix, \( C_F \in \mathbb{F} \), will be defined similarly as

\[
C_F = \frac{1}{N} \sum_{i=1}^{N} \Phi(x_i)\Phi(x_i)^T.
\]

We assume that \( \Phi(x_i) \) are centered in feature space. Consider \( v_i^F \), the \( l-th \) eigenvector of \( C_F \) and \( \lambda_i \) its \( l-th \) eigenvalue. We can define a kernel \( N \times N \) matrix

\[
K_F(x_i, x_j) = (\Phi(x_i) \cdot \Phi(x_j)),
\]

which allows us to compute the value of dot product in \( \mathbb{F} \) without carrying out the map \( \Phi \). The kernel function has to satisfy the Mercer’s theorem to ensure that it is possible to construct a mapping into a space where \( K_F \) acts as a dot product. The projection of a new test point, \( \mathbf{n} \), is given by

\[
(\mathbf{v}_l^F \cdot \Phi(\mathbf{n})) = \sum_{i=1}^{N} \lambda_i \alpha_i^l K_F(x_i, \mathbf{n}),
\]

where \( \lambda_i \) is defined by the solutions to the eigenvalue equation \( N \lambda \alpha = K_F \alpha \).

It is important to stress that all the arguments shown in this appendix rely on the assumption that the data are centered in feature space. Where the centered kernel matrix, \( \tilde{K}_F \), can be expressed in terms of the non-centered kernel matrix, \( K_F \), as

\[
\tilde{K}_F = K_F - 1_N \lambda_1 K_F - K_F 1_N + 1_M K_F 1_N,
\]

where \( (1_N)_i = 1/N \). The reader should be aware that we always refer to the centered kernel matrix \( \tilde{K}_F \). However, for the sake of simplicity, the tilde is not used in our notation.

Finally, we need to choose a form for the kernel function \( k(x_i, x_j) := K_{F,i,j} \). For the sake of simplicity, we make an a priori choice of using a Gaussian kernel.

\[
k(x_i, x_j) = \exp \left[ - \frac{||x_i - x_j||^2}{2\sigma^2} \right],
\]

where the value of \( \sigma \) is determined by a cross-validation process.

E2 The k-Nearest Neighbor algorithm

The kNN begins with the training sample organized as \( q_i = (x_i, y_i) \), where \( x_i \) is the \( i-th \) data vector and \( y_i \) its label, and a definition of distance between 2 data vectors \( d(x_i, x) \). Given a new unlabelled test point \( q_l(x_l, \cdot) \), the algorithm computes the distance between \( x_l \) and all the other points in the training sample, \( d(x_l, x) \), ordering them from lower to higher distance. The labels of the first \( k \) data vectors (the ones closer to \( x_l \)) are counted as votes in the definition of \( y_l \). Finally, \( y_l \) is set as the label with highest number...
of votes. Throughout our analysis, we used an Euclidean distance metric and order $k = 1$.

### E3 Cross-validation

The main idea behind the cross-validation procedure is to remove a random set of $M$ data points, $T^{\text{out}}$, from the sample. The remaining part is given as input for a given classifier algorithm and used to classify the points in $T^{\text{out}}$. In this way, we can measure the success rate of the classifier over different random choices of $T^{\text{out}}$ and also compare results from different classifiers given the same training and $T^{\text{out}}$ sets (see e.g., Arlot & Celisse 2010).

The number of points in $T^{\text{out}}$ is a free parameter and must be defined based on the clustering characteristics of the given data set. Here we chose the most classical exhaustive data splitting procedure, sometimes called Leave One Out (LOO) algorithm. As the name states, we construct $N$ sub-samples $T^{\text{out}}$, each one containing only one data point, $M = 1$. The training sample is then cross-validated and the performance judged by the average number of correct classifications.

Data exhaustive algorithms like LOO have a larger variance in the final results, although, they are highly recommended for avoiding biases regarding local data clustering and some non-uniform geometrical distribution of data points in a given parameter space.
